ABSTRACT
This study investigates flow around a circular cylinder in forced two-degree-of-freedom motion at four different phase angles between the transverse and in-line cylinder motion, at a Reynolds number of 250. Time-mean and rms values of force coefficients and mechanical energy transfer are investigated against frequency ratio in the lock-in domain. Computations were carried out by an in-house finite difference code developed by the author. Results reveal that an increase in phase angle, by bending the figure-eight cylinder path downstream, can reduce drag. Mechanical energy transfer was mostly positive, meaning that energy is transferred from the fluid to the cylinder, leading to a potentially dangerous VIV situation. The change in the initial conditions resulted in hardly any changes in the results.

NOMENCLATURE
- $a_{x,y}$: the dimensionless $x$ and $y$ components of cylinder acceleration
- $A_{x,y}$: amplitude of oscillation in $x$ or $y$ directions, respectively, non-dimensionalised by $d$
- $C_D$: drag coefficient, $2F_D / (\rho U^2 d)$
- $C_L$: lift coefficient, $2F_L / (\rho U^2 d)$
- $d$: cylinder diameter (m)
- $E$: mechanical energy transfer
- $f$: oscillation frequency, non-dimensionalised by $U/d$
- $f_v$: vortex shedding frequency, non-dimensionalised by $U/d$
- $F_D$: drag per unit length of cylinder (N/m)
- $F_L$: lift per unit length of cylinder (N/m)
- $R$: radius, non-dimensionalised by $d$
- $Re$: Reynolds number, $Ud/\nu$
- $St$: non-dimensional vortex shedding frequency, $f_v d/U$
- $t$: time, non-dimensionalized by $d/U$
- $T$: motion period, $1/f_v$
- $U$: free stream velocity, velocity scale (m/s)
- $v_{x,y}$: the dimensionless $x$ and $y$ components of cylinder velocity

Subscripts
- $D$: drag
- $fb$: fixed body
- $L$: lift
- $rms$: root-mean-square value
- $v$: vortex shedding
- $x, y$: components in $x$ and $y$ directions
- $0$: for cylinder motion; for stationary cylinder at same Re; for initial condition
- $1$: on the cylinder surface
- $2$: on the outer boundary of the physical domain

INTRODUCTION
The flow past a single circular cylinder has been studied as a prototype of bluff body flows theoretically, experimentally and numerically. Some examples of these in real life are silos or smokestacks in wind or underwater pipes in a current. When vortices are shed from the structure a periodic force is generated which might lead to the vibration of the structure especially if the damping is small. The motion resulting from this force usually has either one or two degrees of freedom. The most frequently investigated type of one-degree-of-freedom (1-DoF) cylinder motion is the transverse cylinder oscillation. Both experimental and numerical studies have dealt with pure transverse cylinder motion (e.g., Williamson and Roshko, 1988; Lu and Dalton, 1996; Blackburn and Henderson, 1999. Less often investigated is pure in-line cylinder motion (e.g., Cetiner and Rockwell, 2001; Al-Mdallal et al., 2007; Mureithi et al., 2010). However, far fewer investigations have been carried out for combined, two-degree-of-freedom (2-DoF) cylinder motion. In reality, however, both motions are often present, leading to a Lissajous-type path. The vortex-
induced vibration (VIV) arising in such cases can lead to problems such as fatigue and damage of structures.

Kheirkhah and Yarusevych (2010) suggest that where the mass ratio (the ratio of the mass of the vibrating system to the mass of the displaced fluid) is high, as mainly occurs when a structure is oscillating in air, then the frequency of oscillation in in-line and in transverse directions are approximately equal to each other. This can lead to an elliptical path, such as that observed in tube bundles in heat exchangers (Blevins, 1990). Studies by Didier and Borges (2007), Baranyi (2008) and Kheirkhah and Yarusevych (2010), among others, look at elliptical cylinder motion. The occurrence of vortex switches at certain amplitude values was noted (Baranyi, 2008).

A more typical Lissajous-type path, on the other hand, occurs with a low mass ratio, typically found when a cylinder is moving in liquid: cables and pipes submerged in flowing water may undergo fatigue or damage due to this kind of motion. In this case the frequency of the cylinder motion in in-line direction is approximately twice its frequency in transverse direction, as for example found by Jeon and Gharib (2001), Jauvtis and Williamson (2004), and Sanchis et al. (2008). The phase angle difference between in-line and transverse motion $\Theta$ results in different cylinder paths (Jeon and Gharib, 2001). One typical Lissajous curve is a figure-eight-shaped path, while a path in the shape of an arc, or C-shape, has also been observed in the experimental study for an elastically supported cylinder of Sanchis et al. (2008) in the Reynolds number domain of Re=(1.3 to 1.9)x10$^4$ and in the numerical work of Prasanth and Mittal (2009).

Figure-eight paths have been studied to some extent in numerical investigations with forced cylinder motion (e.g., Baranyi, 2011; Peppa et al., 2010). Both studies looked at the influence of the direction of motion along the figure-eight path; i.e., when the path is traced in a clockwise direction in the upper half or lobe of the figure (and naturally anticlockwise in the lower lobe), or vice versa. It was found that the orientation influenced the mechanical energy transfer: anticlockwise motion in the upper lobe (acw) resulted in positive energy transfer, meaning that the fluid tends to amplify the cylinder oscillation, which can easily lead to VIV. Force coefficients were also affected, with higher drag values for acw. Sanchis et al. (2008) found acw orientation in their free vibration study.

In their experimental study of flow around a forced 2-DoF cylinder motion, Jeon and Gharib (2001) investigated regular figure-eight paths and figure-eight patterns with the lobes bent slightly downstream. They state that the phase angle differences found ranged between $\Theta=0^\circ$ and $-45^\circ$. Similar distorted figure-eight paths were also found in Sanchis et al. (2008).

Based on the results of the above-mentioned experimental studies, a numerical simulation can be designed in order to investigate the effect of phase angle difference on the flow past a cylinder in 2-DoF figure-eight motion. Mechanical oscillation is used to simulate flow around the cylinder as a preliminary study, without carrying out a full fluid-structure interaction (FSI) study. While it is true that a direct relationship between results of investigations of free and of forced vibration is difficult to ascertain (e.g., Williamson, 2004), this is a first step towards considering FSI, with special attention to the energy transfer between the cylinder and fluid.

Low-Reynolds number simulation is sometimes criticised for being irrelevant to real-life cases, which almost always involve higher Reynolds (Re) numbers. However, as Newman and Karmiadakis (1995) argue, since many phenomena in flow-induced vibrations are only weakly dependent on Re, they can be fairly accurately simulated even at relatively low Re.

In this numerical study a circular cylinder is placed in a uniform flow at Reynolds number $Re=250$ and mechanically oscillated in two directions, yielding various figure-eight paths (all anticlockwise in the upper lobe) for four phase angle differences. Mechanical energy transfer and the time-mean and root-mean-square (rms) values of force coefficients are investigated.

**COMPUTATIONAL METHOD**

A non-inertial system fixed to the accelerating cylinder is used to compute 2D low-Reynolds number unsteady flow around a circular cylinder placed in a uniform stream. The governing equations are the non-dimensional Navier-Stokes equations for incompressible constant-property Newtonian fluid in a non-inertial system fixed to the accelerating cylinder, the equation of continuity and the Poisson equation for pressure.

On the cylinder surface, no-slip boundary condition is used for the velocity and a Neumann type boundary condition is used for the pressure. At the far region, potential flow is assumed. Computational results show that this approximation results in some inaccuracies near the outer boundary only, and in practice it has no influence on the results of the near-wake flow and forces acting on the cylinder.

Boundary-fitted coordinates are used to impose the boundary conditions accurately. The physical domain bounded by two concentric circles with radii $R_1$ and $R_2$ is mapped into a rectangular computational domain with equidistant spacing in both directions (see Fig. 1). In the physical domain logarithmically spaced radial cells are used, providing a fine grid scale near the cylinder wall and a coarse grid in the far field. The transformed governing equations and boundary conditions are solved by finite difference method. Space derivatives are approximated by fourth order central differences, except for the convective terms for which a third order modified upwind scheme is used. The Poisson equation for pressure is solved by the successive over-relaxation (SOR) method. The Navier-Stokes equations are integrated explicitly and continuity is satisfied at every time step. For further details see Baranyi (2003; 2008).

The 2D code developed by the author has been extensively tested against experimental and computational
results with good agreement being found, (Baranyi, 2008). A systematic comparison with results from the commercial software package Ansys Fluent also yielded very good agreement (Baranyi et al., 2011).

In this study the dimensionless time step is 0.0005, the number of grid points is 481x451, and a relatively large physical domain of $R_z / R = 360$ has been chosen to enhance accuracy.

\[ x_0 = A_x \sin(4 \pi f_x (t-t_0)+\Theta) \]
\[ y_0 = A_y \sin(2 \pi f_y (t-t_0)), \]

where $A_x$ and $A_y$ are the dimensionless oscillation amplitudes and $f_x$ is the frequency of oscillation in transverse direction. Here $t$ and $t_0$ are non-dimensional time, with $t_0$ being the initial condition, and $\Theta$ is the phase angle difference between the two oscillations. The second time derivatives of $x_0$ and $y_0$ give the accelerations that occur in the Navier-Stokes equations.

Jeon and Gharib (2001) suggest that the value of phase angle $\Theta$ tends to drift for free-vibration cases, but is usually in the range of 0 to $-45^\circ$. Different phase angle values result in different cylinder paths. Based on the suggestion of Jeon and Gharib (2001) $\Theta = 0^\circ$, $-15^\circ$, $-30^\circ$, and $-45^\circ$ are investigated here. As shown in Fig. 2, $\Theta = 0^\circ$ gives a symmetric figure-8-path; whereas at $\Theta = -45^\circ$ the path is a figure-8 pattern with the lobes bent downstream. The dimensionless oscillation amplitudes in this study are fixed at $A_x = 0.1$ and $A_y = 0.4$ throughout the study, ensuring slender cylinder paths. The Reynolds number is fixed at $Re = 250$. The independent variable for the investigation is the frequency ratio of $f_x / St_0$ ranging from around 0.7 to 1.1 (in the vicinity of the natural vortex shedding frequency $f_{n} / St_0 = 1$), but limited to within the lock-in domain. Here $St_0$ is the dimensionless vortex shedding frequency for a stationary cylinder at the same Reynolds number. For $Re = 250$ the value $St_0 = 0.20355$ was used (from Posdzienie and Grundmann, 2007).

Since initial condition was earlier found to influence the number and/or location of jumps in the TM and rms values of force coefficients for a cylinder in 2-DoF motion (Baranyi, 2008), computations were carried out for three different initial conditions ($t_0 = 0$, 0.5, 1.0) for $\Theta = -15^\circ$. For the other $\Theta$ values the initial condition was $t_0 = 0$.

The time-history of force coefficients (lift, drag, base pressure and torque), pressure and velocity field are computed. From these data, time-mean (TM) and root-mean-square (rms) values of force coefficients, streamlines, and vorticity contours can be obtained. Where jumps are found when force coefficients are plotted against frequency ratio, pre- and post-jump analysis is carried out by investigating limit cycle curves, time history curves, FFT spectra and vorticity contours.

Throughout this paper the lift and drag coefficients used do not contain the inertial forces originated from the non-inertial system fixed to the accelerating cylinder, except for the determination of the mechanical energy transfer $E$. Coefficients obtained by removing the inertial forces are often termed ‘fixed body’ coefficients (see Lu and Dalton, 1996). The relationship between the two sets of coefficients can be written as

\[ C_D = C_{Dfb} + \pi a_{0x} / 2, \quad C_L = C_{Lfb} + \pi a_{0y} / 2 \]
where \( a_{0x} \) and \( a_{0y} \) are the cylinder acceleration components and subscript ‘fb’ refers to the fixed body (understood in an inertial system fixed to the stationary cylinder), Baranyi (2005). Since the inertial terms are periodic functions, their TM values vanish, resulting in identical TM values for lift and drag in the inertial and non-inertial systems. Naturally the rms values of \( C_L \) and \( C_D \) will be somewhat different in the two systems.

Investigation was restricted to lock-in cases. Lock-in, or the synchronization between vortex shedding and cylinder motion, produces a periodic solution for each of the force coefficients. In this paper, we consider lock-in to be when the vortex shedding frequency is identical to \( f_y \), the frequency of transverse cylinder oscillation.

The non-dimensional mechanical energy transfer originally introduced by Blackburn and Henderson (1999) for transversely oscillated cylinder was extended for a general 2-DoF motion of the cylinder by Baranyi (2008):

\[
E = \frac{2}{\rho U^2} \int_0^T \int_{-\infty}^{\infty} F \cdot v_x dt = \int_0^T \left( C_D v_{0y} + C_L v_{0x} \right) dt, \tag{3}
\]

where \( T=1/f_y \) is the motion period chosen, \( v_{0x} \) and \( v_{0y} \) are the \( x \) and \( y \) components of cylinder velocity. Note that Eq. (3) is valid for 1-DoF cylinder motion as well.

**RESULTS**

In this study, computations are carried out for the flow past a cylinder following a distorted figure-8-path at \( Re=250 \) against frequency ratio \( f_y/St_0 \) within the lock-in domain. Mechanical energy transfer \( E \) between the cylinder and the fluid, time-mean (TM) and rms values of lift \( C_L \), drag \( C_D \), base pressure and torque coefficients are investigated, but for the sake of simplicity only \( C_L \), \( C_D \) and \( E \) values will be shown in the paper. Sudden jumps between state curves were found in some cases; these indicate a sudden change in the vortex structure (Baranyi, 2008). Values just before and just after a jump (vortex switch) are presented in a pre- and post-jump analysis.

**Time-mean and rms values**

At all four phase angle values investigated, the TM of lift and torque coefficients was zero throughout the locked-in frequency domain (not shown here). This has also been found for all transversely oscillated cases investigated by the author. The rms of fixed-body lift, shown in Fig. 3, generally increases with frequency ratio for all \( \Theta \) values. A tendency that can be observed in Fig. 3 above the frequency ratio of 0.84 is that the absolute value of \( \Theta \) increases with \( f_y/St_0 \). Some jumps can be seen in the curves. The curve belonging to \( \Theta = -45^\circ \) is not even continuous, because – in accordance with the findings of Gharib (1999) – for \( \Theta = -45^\circ \) a not-locked-in domain exists that is bounded by two lock-in domains.

The TM of drag versus frequency ratio for the four phase angle values is shown in Fig. 4 in the lock-in domain. It can be seen that the TM of drag decreases with larger absolute values of the phase angle over most of the lock-in frequency ratio domain for the given parameters. Clear changes in behaviour are seen between \( \Theta=0^\circ \) and the other \( \Theta \) values; as the path is bent downstream, the drag is drastically reduced, while sudden jumps in the curve appear, indicating an abrupt switch in vortex structure (see e.g. Baranyi, 2008).
Mechanical energy transfer

Figure 6 shows the mechanical energy transfer $E$ between the fluid and cylinder. For $\Theta=0^\circ$ and at the amplitudes of $A_x$ and $A_y$ investigated, $E$ remained positive throughout the lock-in domain, and practically constant from 0.77 to 0.93. For the other three values, although the largest part of the lock-in domain exhibits positive mechanical energy transfer values, there are some sub-domains where $E$ is negative. Positive $E$ means that energy is introduced into the cylinder and in the case of free vibration, this could well lead to VIV. It can also be seen in the figure that $E$ decreases with larger phase angle differences.

Effect of initial condition

As is well known, a main feature of non-linear systems is that their solutions can be very sensitive to the initial condition. A very small change in the initial conditions can result in a drastic change in the solution. To check whether this is the case here computations for $\Theta=-15^\circ$, first carried out at $t_0=0$, were repeated for $t_0=0.5$ and 1.0 (see Eq. (1)). In contrary to previous findings in Baranyi (2008) for an elliptical path, where the location of jumps was affected strongly by the initial condition, here the solutions basically were independent of the initial conditions: the three curves collapse into one, as can be seen in Figs. 7 and 8. Note that the curve for the TM of drag in Fig. 7 is the same as that denoted by blue empty triangles in Fig. 4, while the mechanical energy transfer curve shown in Fig. 8 is seen also in Fig. 6. Curves for all other variables also coincided for the three different $t_0$ values. For these parameters, it can thus be stated that the initial condition has essentially no effect on the flow.
of space pre- and post-jump results will be shown only for the single case of $\Theta = -45^\circ$, with frequency ratios on the two sides of the jump of $(f_y/St_0)_1=0.8345$ and $(f_y/St_0)_2=0.835$.

The time histories of the periodic part of the fixed body lift for the two frequency ratios are shown against the dimensionless time $t$ in Fig. 9. Pre-jump curves are denoted by red lines and post-jump curves by blue lines in Figs. 9 and 10. As can be seen in the figure, despite the tiny difference in the frequency ratios, the two time-history curves are substantially different.

The limit cycle curves $(C_{Dfb}, C_{Lfb})$ can be seen in Fig. 10 for the pre-jump and post-jump frequency ratios. The very small difference in frequency ratio results in a drastic change in the shape of the two limit cycle curves. Interestingly, both curves have reflection symmetry. This is true for the drag-lift limit cycle curves of every computational point with a periodic solution. This symmetry originates from the fact that the drag is the same for both positive and negative $y_0$ displacement values.

When $C_{Lfb}$ and its time derivative $\dot{C}_{Lfb}$ are plotted only at the multiples of the motion period $T$ a Poincaré map is obtained, which can be interpreted as a discrete dynamical system. Here, we investigate the limit cycle curves $(C_{Lfb}, \dot{C}_{Lfb})$ containing all the points in the phase plane as a continuous function of time, for pre-jump (Fig. 11) and post-jump (Fig. 12) frequency ratios. Again, noticeable differences occur. The curve in Fig. 11 exhibits two cusps, and is much smaller than the post-jump curve in Fig. 12, which is a relatively smooth curve.

Vorticity contours are presented for pre-jump (Fig. 13) and post-jump (Fig. 14) frequency ratio values. The blue lines indicate negative vorticity values (clockwise rotation), and the red lines show positive values (anticlockwise rotation). The contours belong to the same
cylinder position, at \( t=240T \), by which time the solution is fully periodic.

With pure in-line oscillation mirror image switches have been observed, so the pattern remains the same type (in the cases investigated, one pair of vortices is shed in one cycle) (Baranyi et al., 2010). This was probably caused by symmetry-breaking bifurcation (see e.g. Crawford and Knobloch, 1991). For transverse cylinder oscillation no switches were found, and the 2S pattern (a single vortex shed from each side of the cylinder within a single cycle; see Williamson and Roshko, 1988) appears to be typical around \( Re=250 \) (Baranyi et al. 2011). With elliptical motion, the solution flips but appears to move further from the mirror image solution as the transverse component increases (Baranyi, 2008). In this case, the flow patterns do not seem to flip in the vicinity of the cylinder, but a striking difference in flow structure can be seen. Figure 13 shows what appears to be 2P shedding (a pair shed from each side of the cylinder in one cycle), while the post-jump pattern seems to be 2S, rather similar to the Kármán vortex street but with a broader wake.

Mechanical energy transfer also decreases with increasing phase angle difference, but remains mostly in the positive domain, meaning that energy is transferred from the fluid to the cylinder, thus leading to a potentially dangerous VIV situation.

At all four phase angle values investigated, the time-mean of lift and torque coefficients was zero throughout the locked-in frequency domain.

The initial condition had scarcely any effect on the solution for \( \Theta = -15^\circ \).

Where jumps in time-mean or rms values representing vortex switches were identified, pre- and post-jump analysis was carried out, revealing different time-history and limit cycle curves, vorticity contours and even different vortex shedding patterns.

As this study investigated only an anticlockwise direction of orbit, further investigation could include repeating computations for the clockwise case or at other Reynolds numbers or oscillation amplitude values.
